

Set-A

Write a Java program that does the following:

1. Take two strings as input from the user (e.g., string1 and string2), which may contain a mix of letters, digits, and special characters (e.g., "ab4s3F67h%21").
2. From each string, extract only the **odd digits** (digits that are odd numbers, i.e., 1, 3, 5, 7, 9) — ignore all letters, special characters, and even digits.
3. Combine the extracted odd digits (in the order they appear) to form a new number for each string (e.g., if the odd digits found are '3', '7', '1', the number formed should be 371).
4. Print both newly formed numbers, separated by a comma.
5. Take a third input representing a **mathematical operator** (either * or /).
6. Based on the operator entered:
 - If it's *, print the **product** of the two numbers.
 - Otherwise (assume /), print the **quotient** (integer division) of the two numbers.

Set-B

Write a Java program that performs Selection Sort on an integer array.

Given an array {3, 7, 2, 29, 38, 59, 1}:

1. Implement **Selection Sort** to sort the array in ascending order:
 - For each position i in the array, find the index of the **minimum element** in the unsorted portion of the array (from i to the end).
 - Swap that minimum element with the element at position i.
2. Print the fully sorted array using Arrays.toString().
